PREFACE.

—o—

THERE are many engineers and others interested in refrigerating machinery who have felt the want of a book of reference that will enable them to determine, with sufficient accuracy for all practical purposes, what work their machines are doing without resorting to laborious calculations; therefore a number of tables have been prepared to meet this want, and a short treatise on the Theory and Practice of Refrigeration incorporated therewith.

The tables, which have been calculated as accurately as possible, and have been checked by a gentleman of considerable "expert" experience, cover a sufficiently wide range of temperatures and pressures to meet all ordinary, and a good many extraordinary, requirements.

ILTYD I. REDWOOD.

AMMONIA REFRIGERATION.

INTRODUCTORY REMARKS.

THE ammonia "compression" types of freezing machines are now coming so generally into use in large factories and manufacturing establishments where natural ice was formerly employed, that they are of necessity placed directly or indirectly under the supervision of men who, owing to the comparative newness of the subject of ammonia refrigeration in relation to the manufactures, can not be expected to be thoroughly conversant with their theoretical and practical working.

In a great many instances engineers who have charge of these machines only run them by rule-of-thumb methods, and know-

ing nothing about the why and the wherefore are, in the event of the conditions being changed, unable to reason out what will result from the changed conditions, and what other changes ought to be made to counterbalance them.

It is therefore with a view to giving those connected with the running of ammonia refrigerating plants a more intelligent idea of what they are doing—thereby tending to make their work interesting instead of laborious—that this Book has been written.

BEFORE dealing with ammonia refrigeration it is necessary that the different heat terms, etc., that are used in regard to this subject should be thoroughly understood, and they will therefore be explained forthwith.

The terms with which we have principally to deal are :

- (1) British Thermal Unit.
- (2) Mechanical Equivalent of a Unit of Heat.
- (3) Specific Heat.
- (4) Latent Heat.
- (5) Absolute Pressure.
- (6) Absolute Temperature.

BRITISH THERMAL UNIT.

A British thermal unit is the standard unit of heat in this country, and represents the amount of heat necessary to raise the temperature of one pound weight of water one

degree Fahrenheit—the temperature of the water being 32° ; on the other hand, it is the amount of heat given up by one pound of water in cooling one degree Fahrenheit (*i. e.*, from 33° down to 32°).

MECHANICAL EQUIVALENT OF A UNIT OF HEAT.

Joule found, by means of a suitably constructed agitator placed in water and actuated by a falling weight, that the amount of friction caused by a weight of 1 lb. falling a distance of 772 feet, or a weight of 772 lbs. falling a distance of 1 foot, was sufficient to heat 1 lb. of water 1° Fahr. Therefore, the production of one British thermal unit of heat is equivalent to raising a weight of 1 lb. 772 feet, or 772 lbs. 1 foot, and consequently the mechanical equivalent of a unit of heat is 772 foot-pounds.

SPECIFIC HEAT.

Specific heat is the number of British thermal units required to raise the temperature

of one pound weight of any particular substance 1° Fahr., or it may be expressed as the capacity of different substances for heat.

Scientists have proved that a pound of water has a greater capacity for heat than a pound of any other known substance, and therefore water is taken as the standard of comparison, and its specific heat at 32° Fahr. is unity.

Turpentine has a specific heat of 0.472 and the specific heat of mercury is 0.033; from these figures it is understood that to raise the temperature of 1 lb. of turpentine 1° Fahr. 0.472 B. T. U.* will be required, while the same weight of mercury will require only 0.033 B. T. U. to raise its temperature one degree.

If 2 lbs. of water at 32° Fahr. are heated to 42° Fahr., or through 10° , they will absorb (2 lbs. \times 10° \times 1.000 Sp. Ht. =) 20 B. T. U's, but if 2 lbs. of turpentine are heated through the same number of degrees they

* British Thermal Units.

will absorb only $(2 \text{ lbs.} \times 10^{\circ} \times 0.472 \text{ Sp. Ht.} =) 9.44 \text{ B. T. U's.}$

EFFECT OF TEMPERATURE AND PRESSURE ON SPECIFIC HEAT.

The specific heat of substances varies with varying conditions of temperature and pressure, and invariably increases with increase of temperature or pressure. The variation in the specific heat of water at different temperatures is so small that it may be passed unnoticed, but in the cases of certain oils and gases it is considerable: for instance, a mineral oil that has a specific heat of 0.4503 at 85° Fahr. will have a specific heat of 0.4843 at 120° Fahr. Another point in regard to the specific heat of mineral oils is the fact that as the weight (specific gravity) of the oil "increases" the specific heat "decreases." Also, in the case of paraffin waxes, the higher the melting point the lower the specific heat.

EFFECT OF PRESSURE ON SPECIFIC HEAT OF AMMONIA GAS.

The effect of pressure on the specific heat of ammonia gas is very marked, for whereas the specific heat is only 0.508 when the gas is under a pressure of 28 lbs. or less on the square inch, it is raised to 0.532 when the pressure reaches 80 lbs. or upwards.

The specific heat of a gas when expansion is allowed and when mechanical work is performed is greater than the specific heat of a gas that is not allowed to expand; in other words, specific heat of a gas with constant pressure is greater than the specific heat of a gas with constant volume. In order to understand this more clearly, the following explanation must be given:

SPECIFIC HEAT OF AIR WITH CONSTANT PRESSURE.

Let Figure 1 represent a cylinder with a cross sectional area of 144 square inches (one

square foot) tightly closed at both ends and fitted with a piston, B, that will move without

friction, and let the piston weigh 2,116.2 lbs. Now, if a perfect vacuum is maintained in the space A, and if C contains 1 lb. of air ($= 12.387$ cubic feet) at a temperature of 32° Fahr., the air will be under a pressure of 14.696 lbs. per square inch, and will maintain the piston at a height of 12.387 feet. If this air is now heated to 33° Fahr.—thus raising its temperature 1° Fahr.—its volume will be increased, but the pressure will be exactly the same as before, because the piston has risen to make room for the increased volume of the air. According to Regnault's determinations, the amount of heat that would be necessary to raise the temperature of the air 1° Fahr. under the above conditions, would be 0.2379 B. T. U. Therefore the specific heat of air with constant pressure is 0.2379.

Fig. 1

SPECIFIC HEAT OF AIR WITH CONSTANT
VOLUME.

In the experiment just cited, not only was the temperature of the air raised 1° Fahr., but, owing to its expansion, a certain amount of mechanical work was performed when the piston was raised. Now, by heating the air 1° Fahr., its volume was increased (see page 16) to $(12.387 \times \frac{458.4 + 33^{\circ}}{458.4 + 32^{\circ}} =) 12.41226$ cubic feet, therefore the piston was raised from 12.387 feet up to 12.41226 feet, or through 0.02526 of a foot. As already mentioned, the piston weighed 2,116.2 lbs., therefore the amount of work done by the expansion of the air was $2,116.2 \text{ lbs.} \times 0.02546$, height raised = 53.4552 foot-pounds. As it is known that the mechanical equivalent of a unit of heat is 772 foot-pounds, it is seen that the amount of heat that was required to perform the mechanical work of raising the piston was $53.4552 \div 772 = 0.06924$ B. T. U. Therefore, if the air had been heated from 32° up to 33° Fahr. without being allowed

to expand and perform mechanical work, the amount of heat that would have been necessary would have been $(0.2379 - 0.06924 =) 0.16866$ B. T. U. ; hence the specific heat of air with constant volume is 0.16866.

LATENT HEAT.

Latent heat is heat that is hidden or is absorbed (without making itself apparent to the thermometer) when a solid passes to the liquid state, or a liquid to the gaseous state.

There are, therefore, two kinds of latent heat, one being the latent heat of liquefaction and the other the latent heat of vaporization.

LATENT HEAT OF LIQUEFACTION.

If 1 lb. of ice at 32° Fahr. and 1 lb. of water at 33° Fahr. are placed in separate vessels of exactly the same size and shape, and these vessels are put in a place that is perfectly free from draughts and where the temperature is stationary at, say, 50° Fahr.,

it will be found that the ice will take about 21 times as long to melt and heat up to, say, 40° Fahr. as the water will take to heat up to the same temperature. Now it is quite plain that if both vessels are exposed to exactly the same temperature, their contents must each be absorbing heat at the same rate, and as the temperature of the water in rising from 33° to 40°, or through seven degrees, only required 1-21st of the time that the ice took, the ice must have absorbed $(7 \times 21) = 147^\circ$ Fahr., but only 8° (32° to 40°) of this had been registered by the thermometer, and therefore 139° Fhr. had become latent or hidden. Of course this is but a crude method of determining latent heat, and accurate determinations have fixed 142.4 as the latent heat of ice.

LATENT HEAT OF VAPORIZATION.

If water is heated in an open vessel it will be found that the temperature can not be raised above 212° Fahr. No matter how long the heat may be applied the tempera-

ture will remain stationary, although the water is constantly receiving additional heat. The heat thus hidden in the water is called the latent heat of vaporization, and if 1 lb. of steam at 212° Fahr. were passed through a condenser and converted into 1 lb. of water at 212° Fahr. it would be found that, although the condensation of the steam to water had not affected the temperature sufficiently to be noticeable by the thermometer, the condenser would have absorbed 966 B. T. U's, or sufficient heat to have raised the temperature of over $6\frac{1}{4}$ lbs. of water from 60° Fahr. up to 212° Fahr.

The latent heat of vaporization of water is therefore 966.

LATENT HEAT OF WATER.

It is thus seen that to convert 1 lb. of ice at 32° Fahr. into 1 lb. of steam at 212° Fahr. requires:

Ice at 32° to water at 32° (latent) . .	142.4
Water at 32° to water at 212° . . .	180.0
Water at 212° to steam at 212° (latent)	966.0

1,288.4 B. T. U's;

or the amount of heat that would reduce about $2\frac{1}{2}$ lbs. of cast-iron or about 9 lbs. of silver to the molten state.

In making a great many calculations in regard to heat it is necessary to make use of absolute pressures and temperatures.

ABSOLUTE PRESSURE.

Absolute pressure is pounds per square inch above a vacuum, and, as steam gauges are adjusted so that the O, or zero mark, represents the atmospheric pressure, it is necessary to add 14.7 lbs. to the guage pressure, in order to convert it into absolute pressure.

ABSOLUTE TEMPERATURE.

In regard to absolute temperature experiments have proved that all pure, dry gases expand very nearly to the same extent for equal increments of heat, and it therefore matters little what gas is taken for the purpose of explaining the principle on which the basis for absolute temperatures has been determined.

Let Fig. 2 be a cylinder closed at both ends, and having a cross sectional area of 144 square inches (1 square foot), a depth of about 18 inches, and a piston, B, capable

Fig. 2

of moving without friction. It must now be supposed that the space C contains 1 cubic foot of air at a temperature of 32° Fahr., and that the piston, B, is weighted so as to exert

a pressure of 14.7 lbs. on the square inch, while a perfect vacuum is maintained in A. Regnault's experiments have proved that if the contents of C are now heated to 212° Fahr., or through 180° Fahr. (*i. e.*, $212^{\circ} - 32^{\circ}$), the piston and its load will be raised 0.367 foot, or to D, and the cubic foot of air will be increased in volume to 1.367 cubic feet.

If we start again with the temperature at 32° Fahr. and the piston at E, and extract instead of add 180° Fahr. of heat (*i. e.*, cool down the contents of C to -148° Fahr.), the piston will descend the same distance that it rose when the air was heated, namely, 0.367 foot, or to F. The extraction of another 180° Fahr. by cooling down the contents of C to -328° Fahr., would cause the piston to again descend another 0.367 foot, or to G, and to cause the piston to descend to H (and thus contract the air in C to, theoretically speaking, nothing), would necessitate the air being cooled down $\frac{180}{367} = 490.4^{\circ}$ Fahr. below 32° Fahr. or to 458.4° Fahr. below zero.

ABSOLUTE ZERO.

Absolute zero is -458.4° Fahr., and an absolute temperature is the absolute zero temperature, plus the ordinary thermometer reading. The absolute temperature of a gas at 32° Fahr. is 490.4 ($458.4 + 32^{\circ}$), and if the temperature were 0° Fahr. the absolute temperature would be 458.4 , while if the temperature were -32° the absolute temperature would be 426.4 ($= 458.4 - 32^{\circ}$).

With the aid of this knowledge it is now easy to understand how the volume of gases at different temperatures is computed by the formula $v = V \times \frac{458.4 + t}{458.4 + T}$, in which

V = Volume of the gas at the original temperature, T .

v = volume of the gas at the new temperature, t .

EFFECT OF PRESSURES ON VOLUME OF GASES.

The volume of gases is also altered by pressure, and, according to Marriotte, the

volume of any gas varies inversely as the pressure—the temperature remaining constant. Thus: one cubic foot of air at 10 lbs. absolute pressure on the square inch, if subjected to an absolute pressure of 100 lbs., will be reduced in volume to (1 cubic foot \times 10 lbs. \div 100 lbs. =) 0.1 cubic foot, provided the work of compressing is done without generating heat. But it is known that when work is done, heat is necessarily generated, and if the cubic foot of air at 10 lbs. absolute pressure is compressed to 1-10th its volume by being subjected to an absolute pressure of 100 lbs., its temperature will be raised to about 810° Fahr. Therefore, in calculating the volume of a gas that has been subjected to pressure, it is necessary to take into consideration the changes in volume caused by both temperature and pressure together, and the general formula becomes:

$$V \times \frac{P}{p} \times \frac{458.4 + t}{458.4 + T} = v,$$

in which V, P and T, and v, p and t, are the respective volumes, pressures and tempera-

tures of the gas before and after compression. Thus, if

1 cubic foot of air..... = V
 at 20 lbs. Absolute Pressure..... = P
 and 60° Fahr. temperature..... = T
 is heated to
 600° Fahr. temperature..... = t
 by being subjected to
 200 lbs. Absolute Pressure..... = p
 it will be reduced in volume to:

$$1 \text{ cubic foot} \times \frac{\text{Pres.}}{200} \times \frac{\text{Temp.}}{\frac{458.4 + 600}{458.4 + 60}} = \underline{0.2 \text{ cubic ft.}} \dots v$$

CHAPTER II.

THEORY OF REFRIGERATION.

A CAREFUL study of the foregoing pages ought to have made the two following facts quite plain:

1. In order to effect the expansion of a

gas it is necessary that the gas should absorb heat.

2. The act of compressing a gas generates heat.

FREEZING BY COMPRESSED AIR.

If a compressed gas is re-expanded it practically absorbs the same amount of heat that was generated by compression, and the re-expanded gas will therefore be cooled down to its original (*i. e.*, before compression) temperature. The gas in this case will simply absorb the heat necessary for its re-expansion from itself; but if, on the other hand, the compressed gas is cooled down before it is allowed to re-expand, it is very evident that it will not contain sufficient heat in itself to effect its own expansion, and therefore it will have to extract the necessary heat from its surroundings, and by so doing it will produce the sensation of cold, although, strictly speaking, cold can not be produced, as it is a negative condition.

The following example will make the foregoing explanation plainer:

1 lb. of air at.....14.7 lbs. Abs. Pres.
 and.....60° Fahr.
 if compressed to.....110 lbs. Abs. Pres.
 will have its temperature raised to..475° Fahr.
 This compressed air is now cooled to..65° Fahr.
 or through.....(475° — 65°).....410° Fahr.
 As the specific heat of air is 0.238,
 the number of thermal units that
 have been extracted from the com-
 pressed air are...(410 × 0.238)....97.58.

If this cool compressed air is now re-expanded to its original absolute pressure of 14.7 lbs., it will have to absorb 97.58 B. T. U's. As the extraction of 170 thermal units from 1 lb. of water whose temperature is 60° Fahr. will convert the pound of water into a pound of ice, it is evident that if the 1 lb. of above compressed air at a temperature of 65° Fahr. is expanded in a suitable apparatus surrounded by $(97.58 \div 170 =) 0.574$ lb. of water at 60° Fahr. temperature, the water will be converted into 0.574 lb. of ice of 32° Fahr. temperature.

The above figures are only approximately

correct, and are simply given as an illustration of the theory of freezing by compressing and re-expanding a gas (such as air) that is not liquefied by compression.

FREEZING BY AMMONIA.

In considering the theory of refrigeration by means of the liquefiable gas ammonia it will be seen that the great advantage of ammonia over air lies almost entirely in the latent heat of vaporization.

Suppose 1 lb. of ammonia gas at 20 lbs. absolute pressure and 32° Fahr. is compressed to 110 lbs. absolute pressure, its temperature will thereby be raised to 268.6° Fahr. If the compressed gas is cooled to 65° Fahr. its temperature will be lowered 203.6° , and this number of degrees multiplied by the specific heat of ammonia gas (which in this case is 0.532) shows that 108.31 thermal units have been extracted from the gas. But if instead of cooling the compressed gas to only 65° Fahr. it is cooled to 60° Fahr., it will be converted into a liquid, and as the

latent heat of vaporization of ammonia at 110 lbs. absolute pressure is 517.23, the following will now be the number of thermal units extracted. Temperature of compressed gas was 268.6° Fahr., and if cooled to 60° Fahr. its temperature will be lowered 208.6°.

Degrees cooled × specific heat.....	= 110.97 T. U's.
Latent heat of vaporization.....	= 517.23 “

Therefore total thermal units extracted = 628.20

These figures show how the advantage derived by the use of ammonia in the place of air lies in the comparative ease with which ammonia gas can be liquefied, thereby allowing of use being made of its latent heat of vaporization.

CHARACTERISTICS OF AMMONIA.

Ammonia is a colorless, irrespirable gas, with the odor of hartshorn. It is feebly combustible if mixed with a large proportion of air, and burns with a greenish-yellow flame; if mixed with about twice its volume of air it explodes with some violence. It

is only a little more than half the weight of air, is exceedingly soluble in water, and has a very strong action on copper and its alloys. The characteristics of ammonia render it necessary that the following precautions should be observed in regard to the handling of it and in constructing an ammonia refrigerating plant.

EXPLOSIVENESS.

Owing to the explosiveness of the gas it is important that any part of an apparatus should be thoroughly aired before a naked light is brought near it. This precaution is sometimes ridiculed by those who, through good luck rather than good management, have never exploded any large volume of the gas; but the author has personal knowledge of a case where a man was thrown from a scaffold by the violence of an explosion which took place when the man lowered a lighted candle into a tall cylinder used in connection with ammonia refrigeration by the absorption process.

TENDENCY OF THE GAS TO RISE.

When a pipe that conveys ammonia bursts, anybody who happens to be near it should keep his head as low as possible while effecting his escape, because the gas being only half as heavy as air naturally rises as soon as it is liberated into the air; if a man stood erect he might possibly be overcome by the gas, while if he stooped he would, in a great many cases, escape without experiencing any bad effects.

SOLUBILITY IN WATER.

As ammonia is exceedingly soluble in water (so much so that 1 part of water will at 60° Fahr. absorb about 800 parts of the gas) the latter should be used to "kill" the gas in the event of any considerable quantity of strong ammonia solution being spilt. Also, in the case of a man going to the rescue of anybody who is overcome by the gas, he should first take the precaution of placing a piece of waste or rag soaked with water

over his nose and mouth before entering the atmosphere that is impregnated with ammonia.

ACTION ON COPPER.

No part of an ammonia apparatus with which the ammonia is liable to come directly in contact must be constructed of copper or any of its alloys, such as brass, bronze, etc., as the parts containing that metal will be rapidly eaten away.

26° AMMONIA.

Commercial liquid ammonia, commonly known as "spirits of hartshorn," is a solution of ammonia gas in water. In the wholesale trade it is sold in large iron drums, and as its usual strength is 26° Beaumé, it is known as "26° ammonia."

ANHYDROUS AMMONIA.

The other commercial preparation of ammonia is liquid anhydrous ammonia, and it

must not be confounded with the ordinary liquid 26° ammonia. The difference between the two is that the liquid anhydrous (from the Greek *vdōr*—meaning without water) ammonia is the pure, dry, ammonia gas compressed to a liquid, while the 26° ammonia, as we have already seen, is a solution of the gas in water.

CHAPTER III.

GENERAL ARRANGEMENT.

USERS of ammonia refrigerating machines arrange their plant in a manner that best suits their special requirements or accommodations; but wherever it is practicable the whole of the plant should be as compact as possible, so that the possibility of loss of refrigerating effect due to the absorption of heat by long connections from the surrounding atmosphere may be reduced to a minimum.

Figs. 3 and 4 show the principal parts of an ammonia plant, arranged so that the following explanation can be easily followed and understood:

DESCRIPTION OF THE PLANT.

When the plant is in working order the liquid anhydrous ammonia is contained in the receiver, E, and the bottom two or three coils of the condenser; and being under a gauge pressure of, say, 120 lbs., it flows through the pipe F and the manifold G to the expansion valves, H. Passing through the expansion valves, the ammonia traverses a series of pipes or coils which are surrounded by brine in the refrigerator, I, and terminate in the manifold K, that leads to the suction of the compressor, A. The suction of the compressor maintains a gauge pressure of, say, 28 lbs. in these series of pipes, and thereby relieves the ammonia of its high pressure as soon as it passes the expansion valves. Directly the liquid anhydrous ammonia experiences this relief of pressure it commences

Fig. 4

to boil, or vaporize, and in so doing it extracts heat from the brine, which latter could be cooled down to the boiling point of the ammonia due to a suction pressure of 28 lbs., namely, to 14° Fahr. By the time the ammonia reaches the manifold K it has been entirely vaporized, and therefore passes off in the gaseous state, and entering the compressor by the pipe L it is compressed and then discharged through the pipe B into the separator, C, where any of the oil (used for lubricating the compressor) or other foreign matters that are mechanically carried forward by the gas are separated, and the gas then enters the condenser, D, where it is again liquefied and, running down into the receiver, E, recommences the above-described movements.

CONSTRUCTION DETAILS—THE COMPRESSOR.

Owing to the heat that is generated during the compression of ammonia gas it is necessary that the compressor shall be surrounded,

or jacketed, with water, so as to prevent the overheating of the cylinder, etc., and undue abrasion of the rubbing surfaces. The horizontal type of compressor is usually jacketed from end to end, but the heads are not artificially cooled.

A, Fig. 3, is a half-sectional end view of a horizontal compressor. The cylinder, *a*, and jacket, *b*, together with the gas passages, *f* and *g*, in Fig. 4, are cast in one piece, which is bolted to the engine frame, G. The passage *g* supplies the two suction valves, *d* and *k*, while the discharge valves, *e* and *l*, connect with the passage *f*. The jacket is supplied with water by the pipe *p*, the water filling up the space *h* and overflowing through *r*. The cylinder heads, *i i*, which contain the valves, ports and passages leading to *f* and *g*, are held in place by the bolts, *s*.

In the vertical type of compressor the water-jacket is built so that the water not only surrounds the compressor cylinder but also entirely submerges the cylinder head and its valves. The relative efficiency of the two types of compressors will be com-

pared under the heading "Indicator Diagrams."

STUFFING-BOXES.

One of the principal sources of loss of ammonia in a refrigerating plant is in the stuffing-boxes of the compressor. The stuffing-boxes in some of the vertical types of compressors are packed with lead or babbitt-metal rings cut with a bevel, so that when they are subjected to pressure every alternate one hugs the piston-rod, while the others are pressed tightly against the inner surface of the stuffing-box, thus forming a tight yet smooth working packing. In the vertical compressor, which is only single-acting, the pressure on the packing does not exceed 28 lbs. on the square inch, while with the horizontal compressor, which is double-acting, the pressure may reach and even exceed 165 lbs., according to the temperature of the condensing water. For this reason it is necessary that the packing for stuffing-boxes in a horizontal compressor

stuffing-box shall be deep. The depth is usually 12 inches, and the annular space between the piston-rod and the inside of the box is about $\frac{5}{8}$ of an inch. It requires a considerable amount of attention which is more or less proportional to the condensing pressure, but more especially to the kind of packing that is used, and it is with a sense of the benefit that the user will derive that "Common Sense," "Garlock's," and "Selden's" packings are recommended as being specially suitable (if used conjointly) for horizontal compressor stuffing-boxes. The most satisfactory way to employ this combination packing is to, first of all, pack the stuffing-box to a depth of 5 to $5\frac{1}{2}$ inches with Common Sense packing; then, having placed the perforated ring in position, half fill the rest of the box with Garlock's packing and finish off with Selden's packing.

The packing should be driven tightly home, piece by piece, and then the gland should be screwed on only hand-tight, so as to allow the packing room to expand and fill the spaces without undue pressure. If the

packing is forced into the stuffing-box by means of the gland, and is not allowed room to expand, it will last but a very short time, and give trouble as long as it does last.

SPECIAL LUBRICATION.

The hot ammonia gas under high pressure will cut through the best packing in a very short time if a liberal supply of oil is not forced into the stuffing-box at intervals of an hour or so. To effect the thorough lubrication of the packing it is necessary that a hole shall be tapped in the centre (longitudinally) of the stuffing-box, which is then connected by a $\frac{1}{4}$ -inch pipe with a small hand force-pump. The packing is divided into two portions by a perforated iron ring, which ring is directly opposite the above-mentioned hole, so that when the oil is delivered by the pump it is distributed through the perforations to the packing on either side of the ring.

OIL FOR LUBRICATION.

On no account must any animal or vegetable oils be used for lubricating the compressor, because as soon as any of these oils come in contact with the ammonia they will form soaps that will give endless trouble and annoyance. Nothing but a mineral oil of high viscosity and guaranteed purity should be used.

CLEARANCE SPACE, ETC.

It is very essential that there shall be no unnecessary spaces, such as screw-slots, deep ports, etc., on the inside of the compressor cylinder, and the clearance space between the piston and cylinder head should not exceed $\frac{1}{32}$ to $\frac{3}{64}$ of an inch. If attention is not paid to these particulars too much gas will remain in the cylinder after the piston has completed its stroke, and the re-expansion of this clearance-space gas as the piston recedes will greatly diminish the working capacity of the cylinder.

SUCTION AND DISCHARGE VALVES.

The suction and discharge ports are closed by poppet valves. The discharge valve, Fig. 5, screws into the outside of the cylinder head, and the spring, *a*, presses the valve

Fig. 5

Fig. 6

against the seat on the inside of the head. The suction-valve, Fig. 6, screws into both the outside and inside of the cylinder head, and the gas in G, Figs. 3 and 4, passes in

through the holes, *a*, in its passage to the cylinder. The spring, *b*, is held in its place by the nut, *c*.

EFFECT OF EXCESSIVE VALVE-LIFT.

The lift of the valves is of very great importance, as it materially affects the refrigerating effect of a machine. If the lift is too great the valve will not act with sufficient quickness, and especially is this so in the case of high-speed compressors, in which an additional valve-lift of $\frac{1}{8}$ of an inch will cause a diminution of one ton refrigerating effect in 24 hours.

REGULATION OF VALVE-LIFT.

The lift of the discharge valve is regulated by the plug, *b*, against which the valve-stem strikes, the distance between the striking surfaces being regulated by the thickness of gasket, *c*. In the case of the suction-valve,

the lift is regulated by means of an iron sleeve around the valve-stem against which the nut, *c*, strikes when the valve opens.

CHAPTER IV.

THE SEPARATOR.

OWING to the large volume of oil that is, or should be, used for lubricating the stuffing-box of the compressor, it is evident that a considerable quantity of it must pass into the cylinder and be carried through the discharge valves by the ammonia gas. If this oil were allowed to pass into the condenser it would soon find its way into the rest of the apparatus, and would cause trouble by choking up the expansion valves, etc.; therefore, with a view to obviating this annoyance, a separator is interposed between the compressor and condenser. The usual form of separator is an iron cylinder about 18 inches

in diameter and from 18 to 36 inches high. The ammonia gas enters by a connection on one side and leaves by a connection on the opposite side. The connections are usually 3 or 4 inches from the top, and the gas coming in contact with the side of the cylinder is freed of the most of its oil and passes on to the condenser, while the oil falls to the bottom of the separator. This and most other forms of separators are very imperfect, for the reason that they are not supplied with sufficient contact-surface and are not kept sufficiently cool. The gas when it passes through the separator is at a high temperature, say 200° Fahr., and consequently the oil held in suspension is exceedingly limped and light in weight, and has not any great tendency to separate from the gas. The author would, therefore, advise the construction of a separator on the principle shown in Fig. 7. The cast-iron cylinder, A, with its inlet, E, and outlet, F, opposite one another, has its cover, B, and contact plates, C, cast in one piece, and these are arranged so that when the gas impinges on them it is

Fig. VII

SECTION THRO. X, Y.

distributed over a large surface and is forced against the side of the cylinder in its zigzag passage from E to F. The oil in striking against these division plates will separate from the gas far more readily than if it meets with no obstruction, but even with the aid of the contact plates the separator will not effect a perfect separation unless the oil is rendered more viscous so as to increase its tendency to adhere to the plates, etc. This can be easily accomplished by making use of the water-jacket, D, which will keep the separator cold enough to make the oil separate and fall to the bottom. The bottom of the separator may be connected with the compressor so that the separated oil may be used over again; but this connection is of little or no use with double-acting compressors, because pieces of packing, etc., that find their way from the stuffing-box into the compressor and thence into the separator will soon choke it up. The separator should be periodically cleaned, the cover, B, and plates, C, being raised by the ring, G, after the water has been run off from the jacket

by the cock, I. On no account must the inlet to the separator look down, because the gas will then impinge on the oil lying in the bottom, and will be likely to become more contaminated with, rather than freed of, the oil.

THE CONDENSER.

The shape of the condenser tank affects the efficiency of the condenser to some extent: it should be deep and narrow rather than long and shallow, so that there may be as great a distance as possible between the more or less warm water on the surface and the cold water that is admitted at the bottom. Another important point is to see that the water is properly distributed when it enters the bottom of the condenser, and not allowed to all run in at one point, as in the case of a discharge through an open-end pipe.

CONDENSER-WORM.

The condenser-worm or piping through which the ammonia passes should consist of

about one-third of 2-inch, one-third of 1½-inch, and one-third of 1-inch pipe. This gradual decrease in the size of the pipe will give far less "excessive" condensing pressure than when the gas passes from a manifold into a series of three or four separate one-inch worms. The friction of the gas in passing through a 2-inch pipe is less than when the gas passes through a number of pipes whose aggregate areas are equal to a 2-inch pipe. Another point is, it is quite unnecessary to have the same cross-sectional area for the exit as for the inlet pipe, because the volume of the liquid anhydrous ammonia passing through the exit is only about 1-75th of the volume of the gas that passes through the inlet pipe.

RECEIVER.

The receiver should be capable of holding 4 lbs. of liquid anhydrous ammonia for every 24-hour-ton maximum capacity of the machine. That is to say, if the machine has a maximum capacity of 65 tons of ice in 24

hours, the receiver should be capable of holding $65 \times 4 = 260$ lbs. of liquid anhydrous ammonia.

REFRIGERATOR OR BRINE TANK.

The arrangement of the piping in the refrigerator is different from that in the condenser. By referring to Fig. 3 it will be seen that the liquid ammonia entering the series of piping at the manifold G descends by the vertical pipes, T, and then passes upward through the coils, U, before it is taken into the suction manifold K. The object of arranging the piping in this way is to insure the thorough vaporization of the liquid ammonia when the brine has become cooled down to a point near to the boiling point of the ammonia due to any given suction pressure, and the vaporization is thoroughly effected because any liquid ammonia that does not vaporize will not pass upwards, and therefore the gaseous or vaporized ammonia has to bubble through it, and the liquid thereby absorbs sufficient heat from

the gaseous ammonia to effect the vaporization of the whole. If the liquid ammonia passed in at the higher and out at the lower extremity, as in the case of an ordinary condenser-worm, a large quantity of the ammonia would pass through in the liquid form, as the warmer, or gaseous portion, would not be brought so intimately in contact with it. The refrigerator should be thoroughly insulated, and for this purpose it should be surrounded by a wooden jacket so that there is a space of about 3 to 6 inches between the refrigerator and the inside of the jacket, and this space should be filled with mineral-wool, charcoal, sawdust, or any other good non-conductor.

SIZE OF PIPE AND AREA OF COOLING SURFACE.

The size of pipe and total cooling surface exposed to the brine very materially affect the economical running of a refrigerating plant, and practical results have demonstrated without doubt that coils, or worms, made of 2-inch pipe are far more econom-

ical in regard to the use of steam, etc., than 1-inch pipe. The total length of piping in contact with the brine should be sufficient to give a mean cooling surface of 50 to 55 square feet per 24-hour-ton maximum capacity.

EXPANSION VALVES.

The expansion valves are of the spindle type as shown in Fig. 8, and should be made of the best quality of cast-iron.

WORKING DETAILS.—CHARGING THE PLANT WITH AMMONIA.

In order to charge a new or at any rate an empty plant with ammonia it is first of all necessary to expel the air. This is done

by opening all the valves and cocks with the exception of O, P, and S, which latter are tightly closed, and allowing the compressor to exhaust the air from D, E, F, G, I, K, and L, and discharge it through the open cock N, until the combination vacuum-pressure gauge connected to the suction of the compressor shows that the engine is not capable of exhausting the apparatus any further; the cock N and valve H are then closed and the valve O opened. The drum of anhydrous ammonia (if an anhydrous ammonia generating apparatus is not included in the plant) is now connected with the cock S, which latter is then opened to allow the compressor to transfer the ammonia from the drum. When the plant is charged the cock S is closed and the valves H are then opened sufficiently to allow the compressor to maintain the suction pressure corresponding to the required brine temperature, which will be alluded to later.

CHAPTER V.

AMMONIA TO BE GRADUALLY CHARGED.

THE plant should not be charged with more than 60 per cent. of its full complement of ammonia at its first charging because it is impossible to exhaust the whole of the air from the plant by means of the compressor, and the only way to get entirely rid of the air is by displacement. This is effected by very cautiously opening the cock P once or twice a day and allowing the air to escape, at the same time taking every precaution to prevent undue loss of ammonia. After the air has been displaced a fresh quantity of ammonia is pumped into the plant in the manner above described, and the next day the same operation is gone through again, until at the end of, say, six days, the full complement of ammonia has been charged. In this manner the whole of the air is effectually expelled with but a slight loss of ammonia. An experienced man can easily tell from the general condi-

tions and working of the plant when sufficient ammonia has been charged; but as the uninitiated might experience some difficulty in ascertaining whether the plant was sufficiently charged, the following method has been formulated for calculating the quantity of ammonia that constitutes a full charge.

Suppose the maximum capacity of plant is 65 tons of ice per 24 hours, and that the sizes of the different parts are as follows :

		DIAM.	LENGTH.	CAPAC- ITY. CUBIC Ft.
Connection from Compressor to Sepa- rator.	{B.....2 in.	10 ft.	41.1
Separator		C.....24 "	2 "	
Condenser- Worm.	{	Containing Ammonia as gas.	D ¹ ..1½ "	2800 "
		Containing Ammonia as liquid.	D ² ..1½ "	700 "
Receiver		E.....24 "	3 "	18.3
Connection from Receiver to Refrigerator.....	{	F.....1 "	30 "	
Manifold for Expansion Valves.....		G.....2 "	6 "	
Refrigerating Piping.....		T & U 1½ "	6000 "	
Connection from Refrigerator to Compressor	{	K & L...2 "	10 "	100.3

The parts B, C, and D¹ will contain ammonia in the gaseous state at a gauge pressure of, say, 120 lbs. and average temperature of 80° Fahr.

The parts D², E, F, and G will contain liquid anhydrous ammonia.

The parts T, U, K, and L will contain gaseous ammonia at a gauge pressure of 28 lbs. and an average temperature of 15° Fahr.

TABLE I.

GAUGE PRES- SURE.	TEMPERATURE OF GAS.					
	66°	74°	80°	84°	90°	95°
	Volume of 1 lb. of Gas in Cubic Feet.					
80	3.470					
85	3.292					
90	3.131					
95		3.035				
100		2.900				
105		2.785				
110			2.695			
115			2.590			
120			2.490			
125				2.418		
130				2.333		
135				2.252		
140					2.204	
145					2.134	
150						2.088
155						2.037

From Tables I. and V. it will be seen that the volumes of the ammonia gases at the above *pressures and temperatures* of 120 lbs. and 80° Fahr. and 28 lbs. and 15° Fahr. are respectively 2.490 and 10.763 cubic feet per pound of ammonia; therefore the amount of ammonia required to charge the plant is :

B, C, and D ¹	= (41.1 ÷ 2.49)	16½ lbs.
D ² , E, F, and G.....	= (18.3 × 38.66 *)	707½ "
T, U, K, and L.....	= (100.3 ÷ 10.763)	9⅜ "
		<hr/>
		Total, 733⅜ lbs.
		<hr/>

JACKET-WATER FOR COMPRESSOR.

The amount of jacket-water necessary for the compressor varies according to the condensing pressure. With a low condensing pressure—say 90 to 105 lbs. gauge pressure—10 to 15 gallons of water per hour per 24-hour ton refrigerating effect will usually be found ample, but when the condensing pressure reaches, say, 140 to 150 lbs., the amount of water will have to be increased to about

* Weight of a cubic foot of liquid anhydrous ammonia.

45 to 50 gallons per hour per 24-hour ton refrigerating effect.

JACKET-WATER FOR SEPARATOR.

The amount of water used in the separator jacket should be as large as possible, and so that the water may not be wasted or become expensive, the overflow-pipe, H, should be continued down midway into the condenser, where the water should be distributed and used along with the condensing water that is admitted at the bottom of the condenser.

CONDENSING WATER.

As the pressure against which the compressor has to work is regulated almost entirely by the temperature of the condensed ammonia, it is obvious that the lower the temperature of the condensed ammonia, the greater the saving in the wear and tear of the engine, in the use of steam and consequently the consumption of coal, will be. The quantity and the temperature of the

condensing water are, therefore, points that need careful consideration. The manufacturer who has to use the city water-supply for condensing purposes can not, under ordinary circumstances, economically cool the ammonia to a lower temperature than 55° to 60° Fahr. during the winter months, and 65° to 75° Fahr. during the summer months, because, should he increase his supply of water sufficiently to reduce the temperature of the ammonia, say 10° below the above figures, he would at once incur an extra expense that would not be warranted by the resulting increase in the refrigerating efficiency of the plant. This increased expenditure can, however, be overcome if the following plan is adopted :

LESSENING THE COST FOR CONDENSING WATER.

Instead of supplying the steam-boilers in the establishment with the whole of their water direct from the main, the author advises arrangements being made to draw the

boiler water-supply from the overflow of the ammonia condenser, then making up the deficiency from that source by drawing from the main. This method of working would be beneficial in every respect, because in the first place, the water in passing through the condenser will receive a certain amount of heat which is distinctly an advantage, as boiler-water is, or should be, heated before entering the boiler. Secondly, if the whole or a part of the water required for the boilers is taken from the ammonia-condenser overflow, the cost of condensing the ammonia is practically reduced to *nil*, because the boilers have to be supplied with water, and the fact that that necessary supply has been previously used for condensing purposes in no way increases the cost after the first cost of putting up the system of piping for conveying the water has been paid for. Thirdly, the effect of the use of a superabundance of condensing water will be a reduction of, at least, 30 to 40 lbs. per square inch in the condensing pressure and a corresponding saving in steam.

QUANTITY OF CONDENSING WATER NECESSARY.

If the temperature of the water supplied to the condenser is 55° to 60° Fahr., and the temperature of the overflow or outlet water is 85° to 90° Fahr., the quantity of water that will be required will be about 0.9 gallons per minute per 24-hour ton of ice; but if the temperature of the overflow were only 70° to 75° Fahr. (the inlet temperature being 55° to 60°), the quantity of water that would be necessary would be about $2\frac{1}{2}$ gallons per minute per 24-hour ton of ice. This reduction of fifteen degrees in the temperature of the overflow means a reduction of 30 to 40 lbs. in the condensing pressure, and if the ammonia leaves the condenser at the temperature of the inlet water, a minimum condensing pressure and large saving in steam will result.

LOSS DUE TO HEATING OF CONDENSED AMMONIA.

One very weak point and very surprising oversight in the management of a great num-

ber of refrigerating plants is the fact that, although manufacturers often go to a deal of expense in order to condense and cool the ammonia to the lowest possible temperature, they entirely ignore the importance of making arrangements to maintain that low temperature until the ammonia reaches the refrigerator. The receiver, and a considerable length, if not the whole, of the piping through which the anhydrous ammonia has to pass on its way to the refrigerator are, as a rule, situated in the engine-room—which is not usually the coolest of places—and the temperature of the ammonia is consequently often raised 5, 10, 15, or even 20 degrees (above the temperature at which it left the condenser) before it reaches the refrigerator; and as these 5 to 20 degrees gain in temperature mean a loss of from $\frac{1}{4}$ to $1\frac{1}{4}$ ton refrigerating effect per 24 hours, on a 65-ton machine, it seems as though it would be advantageous to have the receiver and piping covered with a cheap non-conducting material, so as to take full advantage of the benefits resulting from a liberal water-supply to

the condenser, and thus prevent an unnecessary waste.

LOSS DUE.

It might be advisable to here refer to another source of needless loss which has even a greater effect on the refrigerating efficiency of a machine than the case just considered.

SUPERHEATING AMMONIA GAS.

It is the loss incurred by the ammonia gas absorbing heat in the transit from the refrigerator to the compressor. Some people argue that it is absurd to go to any expense for the purpose of preventing that gas from absorbing heat, as it is heated up, any way, as soon as it enters the compressor. Others, again, consider that any heat absorbed by the gas simply means that a few more thermal units will have to be extracted from the gas when it passes into the condenser. If these people would just take time to think, they would at once see that the higher the temperature of the gas is before it enters

the compressor the greater the volume of a given weight must be, and therefore the compressor, although circulating or pumping the same volume, will not circulate so great a weight; and as the refrigerating efficiency of a machine is proportional to the weight of ammonia circulated, it is obvious that the higher the temperature of the gas before it enters the compressor, the smaller the refrigerating efficiency of the machine will be, the suction pressure being the same in both cases. The effect of covering the ammonia pipes is more particularly dealt with under the heading "Directions for Determining Refrigerating Efficiency."

CHAPTER VI.

EXCESS CONDENSING PRESSURE.

THE condensing pressure, when the apparatus is working, is always greater than the theoretical. This "excess" pressure is due almost entirely to the confining of the highly

heated gaseous ammonia in the more or less limited space of the coils of the condenser, and varies greatly according to circumstances. When running at a low suction pressure, say atmospheric pressure, the excess condensing pressure should not be over 5 to 10 lbs., but when running with a suction-gauge pressure of 20 to 28 lbs. the excess pressure will vary from 40 to 60 lbs.

CAUSE OF VARIATION IN EXCESS PRESSURES.

The reason why there is such a large variation in the excess pressure is obvious: with 28 lbs. suction-gauge pressure, the compressor is pumping a three times greater weight of gas than it would pump if the gas were under only an atmospheric pressure, and therefore the condenser is crowded to a greater extent in the former than in the latter case. It may be argued that if the compressor is forcing into the condenser a three times greater weight of ammonia in

one case than in another, the condenser at the same time will be relieved by the expansion valves of a three times greater weight of liquid ammonia, and one will thus counterbalance the other. It is, of course, true that the weight of liquid ammonia passing the expansion valves will be the same as the weight of ammonia gas entering the condenser from the compressor; but as the volume of a given weight of the gas at condensing temperature and pressure is about 75 times greater than the volume of the same weight of liquid ammonia, it is plain that if instead of pumping in 75 volumes of gas into the condenser we increase the amount three times, or to 225 volumes, the increased delivery from the condenser (by means of the expansion valves) of only two volumes is insignificant in comparison with the increased receipt from the compressor, and therefore the increase of excess condensing pressure is what might naturally be expected to accompany increased suction pressure.

OTHER CONDITIONS THAT AFFECT
EXCESS PRESSURE.

No table of the excess condensing pressures for various suction pressures would be of any practical use, because different makes of refrigerating plants give different results. The high speed (140 revolutions per minute) horizontal compressor invariably gives a greater excess pressure than the vertical compressor, which only has a speed of from 40 to 60 revolutions per minute. The method of connecting the condenser piping also affects the excess pressure considerably, and if four separate one-inch pipes, or worms, connected by manifolds are used, the excess pressure will be greater than if one continuous worm (starting at the top with two-inch piping and reducing to one-inch, as recommended in previous pages) is used. Also, the higher the condensing pressure due to the temperature of the condensing water the greater the excess pressure will be.

USE OF CONDENSING PRESSURE IN DETERMINING LOSS OF AMMONIA
BY LEAKAGE.

As the condensing pressure is one of the principal means by which the engineer can tell when the loss of ammonia by leakage has amounted to such a quantity as to render the replenishing of the plant advisable, it is very necessary that the man in charge, if inexperienced, should record in a book the temperature of the condensed ammonia at its point of exit from the condenser, and the suction and condensing pressures, every two or three hours. If these figures are thoroughly memorized and the engineer started with a plant that was fully charged with ammonia he ought to be able, at the end of a month or two, to tell by looking at the suction-pressure gauge, and the temperature of the condensed ammonia whether the condensing pressure was what it should be. For example, suppose the plant has been running for two or three months with an average condensing temperature of 60° Fahr., con-

densing pressure of 120 lbs. and suction pressure of 25 lbs., and that during the next three months the condensing pressure gradually fell to 115 lbs., while the condensing temperature and suction pressure were still 60° Fahr. and 25 lbs. respectively; it would be plain that neither the condensing temperature nor the suction pressure could account for this falling off in the condensing pressure because they have not altered, and therefore it is obvious that the quantity of ammonia can alone account for this alteration. The diminution in the condensing pressure caused by loss or leakage of ammonia is due to the increased condenser space resulting from the leakage, thereby allowing the gas a greater length of worm in which to condense and assume the liquid form, thus lessening the "crowding" of the hot compressed gas.

When the condensing pressure falls off 5 or 10 lbs. the plant should be re-charged with sufficient ammonia to restore the normal condensing pressure.

COOLING DIRECTLY BY AMMONIA.

It is very seldom that ammonia can be used directly for freezing purposes, and in nearly all cases it is used indirectly with brine as a medium. The greatest drawback to using ammonia directly is the liability of ammonia to leak through the fittings, joints, etc., and as meats or other provisions would be rendered valueless as far as the market is concerned by such a leakage, it would be exceedingly risky and injudicious to cool a warehouse directly by ammonia if the only object for so doing was to save the cost of the brine portion of the plant. But in buildings where a slight smell of ammonia would not result in any pecuniary loss—other than the value of the escaping ammonia, which latter if properly looked after will be exceedingly small—it would certainly be advisable to cool directly by ammonia. In this case the expansion valves would be in the building to be cooled, and the ammonia would be expanded in a system of piping hung up on the walls or otherwise conve-

niently arranged. This method of working is decidedly the most economical, as it does away with the necessity of a refrigerator and its long series of piping, the brine pumps and the steam required to run them, the brine piping (4 to 5 inches in diameter) conveying the brine between the pumps, building to be cooled, and the refrigerator, and all the numerous fittings and valves in connection therewith.

BRINE.

Brine is a solution of either common salt (chloride of sodium), chloride of calcium, or chloride of magnesium in water. Brine made of chloride of magnesium is undesirable, as it is liable to contain free acid, which above all other things is most objectionable, owing to its action on metals; whereas common salt, or the "commercial fused" chloride of calcium, are both free from acid. Salt is usually sold by the bag, each bag containing about 200 lbs. and costing about 70c., or \$7.00 per ton. Commercial fused chloride of calcium

is sold in iron drums, holding about 600 lbs. each, and costs about \$16.00 per ton. Cheap common salt, such as may be obtained for 40 to 50 cents per bag, should not be used, as it will be expensive in the long run, and nothing but the purest and best salt should be bought. Common salt for brine making should not contain more than 0.05 per cent. of insoluble matter (calculated on the dry salt). The percentage of moisture is only of account when the salt is bought by weight instead of by the bag, but the percentage of insoluble matter is always of great importance, because, unless there are special facilities for filtering the brine before it enters the refrigerator or system of piping for cooling rooms, etc., it is obvious that if the percentage of insoluble matter is bulky, it will accumulate and eventually settle down in the bottom of the refrigerator and thereby reduce the efficiency of the apparatus by covering the piping, or it is liable to pass into the brine pumps, and from thence to the brine piping for cooling the rooms, where it is likely to lodge in fittings (return bends,

elbows, etc.) and cause serious obstruction. The use of chloride of calcium does not do away with the inconvenience liable to be caused by the presence of insoluble matter, but for temperatures below -7° Fahr. it is absolutely necessary that it should be used for the reason explained in paragraph on "Effect of Composition on Freezing Point."

FREEZING POINT OF BRINE.

Brines will only stand a certain degree of cold without freezing, and the temperature to which brine can be cooled before it will begin to freeze depends, firstly, on the composition of the brine, and secondly, on the strength of the solution.

EFFECT OF COMPOSITION ON FREEZING POINT.

In illustration of the effect that a change in the composition of the brine will have on the freezing point it is only necessary to state that whereas a solution of common salt can

only be cooled to -7° Fahr., a solution of chloride of calcium can be cooled to -40° Fahr.

EFFECT OF STRENGTH ON FREEZING POINT.

In explaining the way in which the strength affects the freezing point of the solution a brine made of common salt will be considered. If a weak solution of common salt in water is gradually cooled, ice will begin to separate out at about 28° Fahr., and this separation of ice with a proportional concentration of the brine will continue till the temperature of -7.5° Fahr. is reached. At this point the brine will contain 24.24 per cent. of salt, and if further cooled will solidify as a whole. If, on the other hand, a saturated solution (at 60° Fahr.) of salt is cooled, salt will separate out, and the brine will weaken until the same temperature and degree of concentration given above is reached, when the solution will become wholly solidified.

SUITABLENESS OF THE BRINE.

For all ordinary purposes, such as ice manufacture, etc., where it is highly improbable that a temperature below -7° Fahr. will be needed, the author would strongly advise the use of a brine made of common salt. The cost is less than one-half of that of chloride of calcium, and it is far easier and more cleanly to handle, because chloride of calcium is highly deliquescent, and therefore a drum of it must be used as soon as opened, otherwise it will absorb so much moisture from the air that it will "run" and cause much annoyance—not to mention loss. As we have already seen, if the brine is either too weak or too strong, a separation will take place—in the former case of ice, and in the latter case of the chemical constituent. Now, if either of these separations occurs it will seriously affect the refrigerating efficiency of a plant, owing to the coating of the refrigerator coils or piping with a bad conducting material such as ice, salt, or chloride of calcium. It is therefore of

the greatest importance that the gravity or strength of the brine should be carefully tried every day, and any variation due to evaporation or other causes should be corrected at once.

MAKING BRINE.

The brine should be made in a separate vessel and not be transferred to the refrigerator until its strength has been carefully adjusted and the dirt, etc., allowed sufficient time to settle to the bottom. If the brine is to be made from salt, the water is first placed in the vessel and carefully measured, and then the requisite quantity of salt—namely, 266.81 lbs.* per 100 gallons of water—is thrown in and the whole stirred either mechanically or manually until the salt is dissolved. The strength of the brine should then be 22° Beaumé. In the case of chloride of calcium the strength can not be regulated to such a nicety as in the case of salt, because the

* These figures are for pure, dry salt, and therefore the percentage of moisture and insoluble matter contained in the salt used must be determined and allowed for.

material has to be placed in the vessel in more or less large lumps, and as these lumps dissolve comparatively slowly at the ordinary temperature it is necessary to boil the water with open steam. This operation, of course, increases the volume of the water first placed in the vessel, and as this increase is an uncertain quantity (according to the size of the lumps and therefore the length of time they take to dissolve) the strength has to be regulated entirely by the use of the hydrometer. It is wiser to make the solution too strong rather than too weak, as it takes less time to reduce the strength by adding water than it does to increase the strength by dissolving more of the chloride of calcium.

CHAPTER VII.

It is advisable to place only 6 gallons of water for every 100 lbs. of chloride of calcium in the vessel to start with, and as soon as the solution is effected cold water should

be added, small quantities at a time, until the strength is reduced to 20° Beaumé.

SPECIFIC HEAT OF BRINE.

According to Professor Denton,* the specific heat of brine made from common salt is as follows :

<i>Strength.</i>	<i>Specific Heat.</i>
20 $\frac{1}{4}$ ° Beaumé	0.818
21 $\frac{1}{2}$ ° “	0.786

The author finds that the specific heat of brine of 22° Beaumé strength and made from American salt is 0.765.

REGULATION OF BRINE TEMPERATURE.

In places where the refrigerating work is regular and the temperature of the brine returning to the refrigerator is not liable to vary many degrees, the regulation of the temperature of the outgoing brine is an easy matter; but where the return brine is sub-

* Transactions of the American Society of Mechanical Engineers, Vol. XII., page 384.

jected to large variations in temperature the regulation of the outgoing brine temperature requires a great deal of attention. In the former case the expansion valves are regulated so that the engine maintains a suction pressure equivalent to a boiling-point (of the anhydrous ammonia) of about 15° Fahr. lower than the brine temperature required. For instance, in ice-making a brine temperature of 25° Fahr. would be the most economical, and 15° lower than that, namely, 10° Fahr., would be the temperature at which the ammonia should boil. By referring to Table III. (page 116) it will be seen that a suction-gauge pressure of 23.85 lbs. is equivalent to an ammonia boiling-point of 10° Fahr., and therefore the expansion valves would need to be regulated so that the engine ran with a suction-gauge pressure of, say, $23\frac{3}{4}$ lbs. If a building has to be cooled and maintained at a temperature of zero, a brine temperature of about -10° Fahr. will be necessary, and 15° lower than that ($= -25^{\circ}$ Fahr.) will be the required boiling-point of the ammonia, and Table III. shows that a suction-gauge

pressure of 1.47 lbs. corresponds to that boiling-point. In both these cases the expansion valves will need little or no attention after they have once been properly regulated; but it will now be shown that if we have a quantity of hot oil that has to be cooled a certain number of degrees Fahrenheit in a given length of time, it is necessary that the expansion valves shall be frequently attended to in order to obtain the desired results. For example:

50,000 lbs. of oil at a temperature of
100° Fahr. have to be cooled to
20° Fahr. or through
80 Fahrenheit degrees in
24 hours, and the specific heat of the oil is
0.750.

In this case the number of thermal units to be extracted from the oil are $(50,000 \times 80 \times 0.750)$ 3,000,000. Now, if the compressor is capable of circulating 43,200 cubic feet of ammonia gas per 24 hours, and the expansion valves are regulated to give, at the commencement, a brine temperature of 15° Fahr., the refrigerating efficiency will be only 2,497,000 thermal units per 24 hours, and it

will therefore take about $29\frac{1}{2}$ hours to cool the oil to 20° Fahr. But if the expansion valves are regulated so that for the first six hours the brine temperature will be 32° Fahr. and during the next 12 hours 25° Fahr., and the remaining six hours 15° Fahr., the refrigerating efficiency will be, approximately :

First 6 hours —	882,000	Thermal units.
Next 12 “ —	1,542,000	“ “
Last 6 “ —	624,000	“ “

Total,	3,048,000	Thermal units,
--------	-----------	----------------

or 48,000 thermal units more than are theoretically required, and 551,000 thermal units more than could be extracted by starting with, and maintaining for 24 hours, the required final brine temperature of 15° Fahr. This great difference in the results is due to the simple fact that the refrigerating efficiency of a plant is proportional to the weight of anhydrous ammonia circulated, and therefore if a large weight of ammonia is circulated at the commencement, when the temperature of the oil is high, and that weight is gradually reduced as the oil becomes cooled, it is evi-

Ammonia Refrigeration.

dent that the oil will be cooled quicker than if the smaller weight, or that necessary for the final temperature, is circulated throughout the whole of the operation. Of course, it would not be advisable to regulate the expansion valves so as to cause the three sudden drops in temperature as in the above example—where it was done for simplicity's sake—but the valves should rather be gradually closed, so that the minimum brine temperature required will be reached about six hours before the material that is being cooled will be required.

INDIRECT EFFECT OF CONDENSING WATER
ON BRINE TEMPERATURE.

If the supply and temperature of the water used in the condenser is irregular the expansion valves will need constant attention (no matter what the nature of the refrigerating work may be), because any irregularities in the condensing water will cause changes in the condensing pressure. If the supply lessens in quantity the temperature of the con-

denser will, of course, rise and cause an increase of pressure. The natural result of increased pressure will be a larger delivery of ammonia forced through the expansion valves, and the suction pressure will in turn also be increased. It is therefore necessary to counterbalance increase of condensing pressure by a proportional closing down of the expansion valves, and decrease in the condensing pressure by opening the expansion valves.

CHAPTER VIII.

DIRECTIONS FOR DETERMINING REFRIG- ERATING EFFICIENCY.

BEFORE going into the details of determining the efficiency of a refrigerating plant it is necessary that one or two points in connection therewith should be explained.

EQUIVALENT OF A TON OF ICE.

The equivalent of a ton of ice is 284,000 British thermal units, or the amount of heat that would be necessary to convert a ton (2,000 lbs.) of ice at 32° Fahr., into a ton of water at 32° Fahr., or, conversely, it is the amount of heat that must be extracted from a ton of water at 32° Fahr. in order to convert it into a ton of ice at 32° Fahr.

COMPRESSOR MEASUREMENT OF AMMONIA CIRCULATED.

Professor Denton's determinations* show that when the ammonia gas enters the compressor it is heated by the walls of the latter and so rarefied as to cause the compressor full of gas to weigh upwards of 25 per cent. less than it would if the gas remained at the temperature of the entrance while the compressor filled.

* Transactions of the American Society of Mechanical Engineers, Vol. XII.

LOSS IN WELL-JACKETED COMPRESSORS.

The make of machine with which Denton experimented was the Consolidated Ice Machine Company's, and the actual loss in the pumping efficiency of the compressors due to the above cause was 21.4 per cent. The compressors (including gas passages, valves, etc.) in this make of machine are exceptionally well arranged for receiving the fullest possible benefit from the jacket-water, and therefore the loss of pumping efficiency is reduced to a minimum. Where compressors are not so efficiently jacketed, the loss by superheating will vary from $21\frac{1}{2}$ to 25 per cent.

LOSS IN DOUBLE-ACTING COMPRESSORS.

An allowance of 30 per cent. for loss by superheating is necessary in the case of double-acting compressors when the gas enters the compressor through the heads and the heads are not jacketed.

Before the efficiency of a plant can be determined it is necessary that the compressor

should be fitted with an indicator, the engine and brine pumps with stroke counters, and that mercury wells should be placed at the following points, viz.:—

DISTRIBUTION OF MERCURY WELLS.

(1) On the discharge pipe, near its point of outlet from the compressor.

(2) On the ammonia discharge pipe from the condenser—immediately at its point of exit.

(3) In the ammonia supply manifold of the refrigerator.

(4) In the ammonia suction—or discharge—manifold of the refrigerator.

(5) In the ammonia suction pipe—immediately at its point of entry to the compressor.

(6) In the return brine pipe, just where it discharges into the refrigerator.

(7) In the brine discharge brine pipe from the refrigerator.

In cases where the pipes are horizontal and of sufficient diameter the mercury well

should be constructed as in Fig. 9, in which A is the pipe, the temperature of the con-

Fig. IX

tents of which is required ; B is the mercury well, made of iron tubing and fitted in the

pipe by means of a bushing. The mercury, C, fills the well about three-quarters full, and in it the thermometer, D, is held by the cork, E.

When the pipes are vertical, or of too small a diameter, the mercury well should be made as follows (Fig. 10):—

The wooden block, B, having a cavity, C, is carefully fitted to the pipe, A, and securely fastened in its place by the iron bands D, D. C is filled three-quarters full with mercury, and the thermometer, E, having been introduced and secured in its place by the cork, F, the whole is so wrapped in hair-felt as to entirely prevent any possibility of the atmosphere having any effect upon the temperature of the mercury.

The portion of the pipe with which the mercury comes in contact should be thoroughly scraped, so as to present a perfectly bright and clear surface, before the wooden block is fastened in its place.

The judicious application of a little soft putty to touching surface of the wood will

make the joint between the wood and pipe perfectly tight and efficient.

Fig. 10.

The most convenient form of thermometer is one with a cylindrical bulb $\frac{7}{8}$ to 1

inch long ; the diameter of the thermometer should be about $\frac{5}{16}$ to $\frac{3}{8}$ of an inch. The graduations should start at a point 3 inches above the top of the bulb and should be

Plan Thro' XY

$\frac{1}{8}$ of an inch apart, and each graduation should represent one degree. With the use of such a thermometer a reading of one-tenth of a degree may be easily and accurately made.

EXAMINATION OF WORKING PARTS.

Having carefully examined the pistons and valves of the brine pumps and compressor, and verified the accuracy of the pressure gauges, a number of tabulated forms should be drawn up ready to receive the readings of the different instruments as they are taken.

NUMBER OF READINGS TO BE TAKEN.

Where a plant is doing "steady temperature" work, such as cooling warehouses or making artificial ice, readings of all the different instruments need not be taken more than once every half-hour; but where the range in temperature of the material to be cooled is large, readings should be taken every quarter of an hour. Diagrams of the steam cylinder and the compressor should be taken every three hours.

CHAPTER IX.

DURATION OF TEST.

FOR steady work, the test should last for twelve hours, and in large range of temperature work the test should last for twenty-four hours, or, at any rate, until the final temperatures agree as closely as possible with those at the start.

INDICATOR DIAGRAMS.

In order to check the brine figures a very careful examination of the indicator diagrams of the compressor must be made, as it is only by the aid of these diagrams that an accurate computation of the volume of ammonia circulated can be made.

Fig. 11 represents the working of a double-acting horizontal compressor running at 140 revolutions per minute. The gauge pressure in the suction discharge pipes of the com-

pressor when the diagram was taken were, respectively, 10 lbs. and 140 lbs. As the diagram shows that the suction pressure in the compressor was only 5 lbs. and the condensing pressure was 150 lbs., it is very evident, in the first place, that both the suction and discharge valves were too small and did

FIG. XI.

not admit of the free passage of the ammonia gas. Secondly, as the suction pressure in the compressor was only 5 lbs. the compressor was not pumping or circulating as much ammonia as the gauge pressure represented. This diagram also shows that the engine had performed 30 per cent. of its for-

ward stroke and 25 per cent. of its return stroke before the pressure due to the re-expansion of the clearance space gas was reduced to the suction pressure—the pressure at which the valves would open. In this case the pumping capacity of the compressor was, therefore, only $72\frac{1}{2}$ per

FIG. XII.

cent. of the piston displacement per revolution.

Fig. 12 represents the working of the same engine after the discharge valves had been enlarged. Although the engine was running at the same speed as before—140 revolutions per minute—the condensing pressure in the

compressor was this time the same as indicated by the gauge on the discharge pipe, showing that the engine had no "excess" pressure to work against, and therefore a saving in steam was effected. The diagram again shows, however, that the suction valves were too small for a speed of 140 revolu-

FIG. XIII.

tions per minute, and, also, that the pumping capacity of the compressor was only $72\frac{1}{2}$ per cent. of the piston displacement.

Fig. 13 is the diagram taken from the same engine when running at the rate of only 120 revolutions per minute. From it we see that the suction valves of the compressor are de-

signed for that rate of speed, and that the previous rates of 140 revolutions per minute were beyond the capacity of the valves.

Fig. 14 was a diagram taken from a compound single-acting vertical compressor running at 40 revolutions per minute, with a suction and condensing gauge pressure of,

FIG. XIV.

respectively, 10 lbs. and 137 lbs. This diagram exhibits an almost perfectly square heel, the loss being only 1 per cent. of the piston displacement, and shows that the suction and discharge valves were of requisite size.

We will now see what these diagrams actually represent in pounds of ammonia cir-

culated per 24 hours, and from those figures we will be better able to realize the importance of this portion of the subject.

For simplicity's sake we will suppose the temperature of the gas entering the compressor was 0° Fahr. in all four cases. The cubical displacement of the piston in the case of the horizontal compressor was 1.30 cubic feet per revolution, and in the case of vertical compressor 4.00 cubic feet per revolution.

$140 \text{ revolutions per minute} \times 1.3 = 182$
 $\text{cubic feet per minute} = 262,080 \text{ cubic feet}$
 per 24 hours.

The indicator diagram shows that 27.5 per cent. of this was lost owing to re-expansion of the gas, and we have seen under sub-heading "Loss in Double-acting Compressors," that 30 per cent. also has, in this case, to be deducted, and therefore the effectual displacement is ($(262,080 - 27.5 \text{ per cent.}) - 30 \text{ per cent.}$) = 133,005 cubic feet per 24 hours.

The suction pressure in the compressor was 5 lbs. (*i. e.*, 19.7, say, $19\frac{3}{4}$ lbs. absolute

pressure). By Table V. (page 125) we see that 1 lb. of ammonia gas at 0° Fahr. and $19\frac{3}{4}$ lbs. absolute pressure = 14.828 cubic feet; therefore the effectual displacement of 133,005 cubic feet = 8,970 lbs. of ammonia circulated per 24 hours.

120 revolutions per minute $\times 1.3 = 156$
cubic feet per minute = 224,640 cubic feet
per 24 hours.

Taking 72.5 per cent. of this amount, and then deducting 30 per cent. of the remainder, we have an efficiency of 114,004 cubic feet per 24 hours.

The suction pressure in the compressor was 10 lbs. (= $24\frac{3}{4}$ lbs. absolute pressure). By Table V. (page 127) we see that 1 lb. of ammonia gas at 0° Fahr. and $24\frac{3}{4}$ lbs. absolute pressure = 11.794 cubic feet; therefore the effectual displacement of 114,004 cubic feet = 9,666 lbs. of ammonia circulated per 24 hours.

In the cases of diagrams 11 and 12, where the engine was running at a speed of 140 revolutions per minute, the pounds of ammonia circulated were only 8,970 as against

9,666 when the engine speed was only 120 revolutions per minute. This increase of 696 lbs. in the circulation of ammonia per 24 hours, together with the smaller consumption of steam (owing to the diminution in the speed of the engine) is due entirely to sufficient time being allowed the ammonia gas in its passage through the suction valves to maintain its suction pressure of 10 lbs., at which pressure 1 lb. of ammonia gas only occupies 11.794 cubic feet. If the piston traveled quicker than the above speed it sucked the gas instead of allowing it to follow by its own pressure, and thereby reduced the pressure to (in the cases of diagrams 11 and 12) 5 lbs., at which pressure 1 lb. of ammonia gas occupies 14.828 cubic feet, and the pumping capacity of the compressor, as far as the weight of ammonia circulated is concerned, is thereby reduced.

40 revolutions per minute $\times 4 = 160$ cubic feet per minute = 230,400 cubic feet per 24 hours.

99 per cent. of this amount equals 228,096 cubic feet, and, as in the case of a thoroughly-

jacketed single-acting compressor, 21.4 per cent. instead of 30 per cent. has to be deducted. The effectual displacement in this case is 179,283 cubic feet per 24 hours.

We have already seen that 1 lb. of ammonia gas at 0° Fahr. and 10 lbs. ($= 24\frac{3}{4}$ lbs. absolute pressure) = 11.794 cubic feet, and therefore the available 179,283 cubic feet = 15,201 lbs. of ammonia circulated per 24 hours.

The actual capacity of this vertical compressor is 230,400 cubic feet per 24 hours as against 224,640 in the case of the horizontal compressor when diagram 13 was taken, or an excess of only 5,760 cubic feet per 24 hours. Yet the increase in the amount of ammonia circulated amounted to (15,201 — 9,666) 5,535 lbs. of ammonia per 24 hours, which figures, if allowance is made for the 5,760 cubic feet excess capacity, are reduced to 5,042 lbs. This enormous increase of 5,042 lbs. in the weight of ammonia circulated is almost entirely due to the fact that the water-jacket on the compressor head of the vertical compressor causes a

complete collapse of the clearance space gas, and thereby allows the suction-valves to open immediately the piston commences its return stroke.

Having ascertained the circulating capacity of our compressor we will now see what the freezing capacity of the plant is and how it could be improved.

We will suppose that the mean results of a 24-hour test were as follows :

Ammonia	{	Gauge Pressure	{	Suction	10 lbs.	
			{	Discharge (Condensing)	140 lbs.	
	{	Temperature	{	at Compressor {	Suction . . .	8° Fahr.
			{	Discharge . . .	251 Fahr.	
			{	at Discharge from Condenser,	62° Fahr.	
{			at Refrig'ator Supply Manifold,	69° Fahr.		
Brine	{	Temperatures	{	" " Discharge "	0° Fahr.	
			{	Leaving Refrigerator	16½° Fahr.	
		Revolutions of Pump per Minute	{	Return to	31¾° Fahr.	
			Strength	{	Revolutions of Pump per Minute	40
		Revolutions of Compressor Engine per Minute			{	Strength
			{	Revolutions of Compressor Engine per Minute	120	

Diagram 13 represented the working of the compressor while the test was being made. The compressor piston displacement was 1.30 cubic feet per revolution.

The displacement of the brine pump piston was 0.8021 gallon per revolution.

AMMONIA FIGURES.—EFFECTUAL DIS-
PLACEMENT.

Compressor: 120 revolutions per minute \times
1.3 = 156 cubic feet per minute = 224,640
cubic feet per 24 hours. This amount less
27.5 per cent. = 162,864 cubic feet, and 30
per cent. deducted from that leaves 114,005
cubic feet effectual displacement per 24
hours.

VOLUME OF GAS.

The gas as it entered the compressor was
at a temperature of 8° Fahr. and under a
gauge pressure of 10 lbs. (= 24.7 lbs. abso-
lute pressure). By referring to Table VI. we
see that 1 lb. of ammonia gas at $24\frac{3}{4}$ (24.75)
lbs. absolute pressure and 8° Fahr. = 12.013
cubic feet and at 24.5 lbs. pressure and 8°
Fahr. = 12.137 cubic feet. Our pressure was
24.7 lbs., or 0.05 lbs. less than $24\frac{3}{4}$, so, as
there are 5, 5-100 difference between $24\frac{3}{4}$
and $24\frac{1}{2}$, we divide the difference in the
volume of the gas at those two pressures by

5 and add the quotient to the figures due to the pressure 24.75 lbs. Thus :

$12.137 - 12.013 = 0.124$; $0.124 \div 5 = 0.0248$. $12.013 + 0.0248 = 12.0378$ cubic feet = the volume of 1 lb. of ammonia gas at 8° Fahr. and 24.7 lbs. absolute pressure.

AMMONIA CIRCULATED PER TWENTY-FOUR HOURS.

The effectual displacement of the compressor was 162,864 cubic feet, and as the volume of one pound of the gas was 12.0378 cubic feet, the amount of ammonia circulated per 24 hours was $(114,005 \div 12.0378)$ 9,470 lbs.

REFRIGERATING EFFICIENCY.

We see by referring to Table III. (page 116) that the latent heat of ammonia at 9.86* lbs. gauge pressure is 561, therefore $(9,470 \times 561 =)$ 5,312,670 thermal units were absorbed by the ammonia in passing from the liquid to the gaseous state (*i. e.*, in ex-

* For all practical purposes these figures are near enough to 10 lbs.

panding), but the average results of the test show that the ammonia entered the refrigerator at a temperature of 69° Fahr. and that the gas left at a temperature of 0° Fahr., it was therefore cooled down from 69° to 0° , or through 69 degrees, and as the specific heat of ammonia at suction pressures is 0.508, as already shown, it is evident $(9,470 \times 69 \times .508) = 331,942$ thermal units were thus utilized in cooling down the ammonia itself, and therefore, not being available for cooling down the brine, they must be deducted from the 5,312,670 thermal units credited to the ammonia, thus leaving $(5,312,670 - 331,942 =) 4,980,728$ effective thermal units, or $(4,980,728 \div 284,800 =) 17.49$ tons of ice per 24 hours.

BRINE FIGURES.—GALLONS CIRCULATED.

The capacity of the brine pumps per revolution was 0.8021 gallon, and as it made 40 revolutions per minute, the volume of brine circulated was $0.8021 \times 40 \times 1440 = 46,200$ gallons* per 24 hours.

* American gallons (= 8.34 lbs. of water).

POUNDS CIRCULATED.

The gravity of the brine was 22° Beaumé, and as brine at that strength weighs 9.84 lbs. per gallon, the number of pounds of brine circulated in the 24 hours was $(46,200 \times 9.84 =) 454,608$.

DEGREES COOLED.

The average temperatures of the brine were :

Return — $31\frac{3}{4}^{\circ}$ Fahr.

Outgoing — $16\frac{1}{2}^{\circ}$ Fahr. Therefore the brine was cooled

$15\frac{1}{4}^{\circ}$ Fahr.

TOTAL DEGREES EXTRACTED.

The total number of degrees Fahrenheit that were extracted from the brine were $(454,608 \times 15.25 =) 6,932,772$.

CHAPTER X.

WE have shown previously that the specific heat of 22° Beaumé brine is 0.765, therefore the number of thermal units extracted were $(6,932,772 \times 0.705 =) 4,887,604$, or $(4,887,604 \div 284,800)$ 17.16 tons of ice per 24 hours. These figures give 0.33 ton of ice per 24 hours less than we obtained from the ammonia figures. This is a result that must always be looked for, as no insulation is perfectly non-conducting, and the air surrounding the refrigerator, etc., is always cooled more or less according to circumstances. The heat imparted to the refrigerator, etc., in this way is a varying amount and can not, under ordinary circumstances, be accurately estimated. It will have been noticed in the average ammonia temperatures that the liquid anhydrous ammonia was heated from 62° Fahr. up to 69° Fahr. in its passage from the condenser to the refrigerator supply manifold. We will now see what

effect this rise in temperature had on the capacity of the plant.

LOSS DUE TO HEATING OF LIQUID AMMONIA.

We have just figured that 5,312,670 thermal units were absorbed by the ammonia in passing from the liquid to the gaseous state, and that 331,942 thermal units of that amount had to be deducted for loss due to cooling the ammonia itself from 69° Fahr. to 0° Fahr.

Let it now be assumed that the temperature of the liquid ammonia remained at its condensing temperature of 62° Fahr. and our figures will be: 9,470 (lbs. of ammonia) \times 62 \times 0.508 = 298,267 thermal units required to cool the ammonia itself from 62° Fahr. to 0° Fahr., and therefore the number of thermal units available for cooling the brine would be (5,312,670 - 298,267 =) 5,014,403, or 17.61 tons of ice per 24 hours. These figures show that the seven degrees Fahren-

heit that the ammonia was heated in its passage from the condenser to the refrigerator represented a loss in the refrigerating efficiency of the plant of $(17.61 - 17.49 =) 0.12$, or one-eighth of a ton of ice per 24 hours.

LOSS DUE TO HEATING OF AMMONIA GAS.

A glance at the average figures again will also show that the ammonia gas in its passage from the refrigerator to the compressor was heated eight degrees Fahrenheit—the gas entering the compressor at a temperature of 8° instead of 0° . To determine what was the lost refrigerating effect in this case it will be necessary to calculate how many pounds of ammonia would have been circulated by the compressor had the temperature of the ammonia gas remained at 0° until it entered the compressor. Reference to Table V. (page 127) shows that 1 lb. of ammonia gas at 24.5 lbs. absolute pressure and 0° Fahr. has a volume of 11.917 cubic feet, and at 24.75 lbs. and 0° Fahr. 11.794 cubic feet;

therefore, at the absolute pressure of 24.7 lbs., the volume of 1 lb. of ammonia gas would be 11.8186 cubic feet. The effectual displacement of the compressor was 114,005 cubic feet per 24 hours, so the number of lbs. of ammonia circulated would be $(114,005 \div 11.8186 =)$ 9,646 per 24 hours. The latent heat of vaporization we have already seen was 561, therefore $(9,646 \times 561 =)$ 5,411,406 thermal units would be absorbed by the ammonia. But the temperatures of the ammonia at the supply and discharge manifolds of the refrigerator were respectively 69° and 0° Fahr., and, consequently, as the ammonia itself had to be cooled sixty-nine degrees, the available number of thermal units would be reduced to $(5,411,406 - (9,646 \times 69 \times 0.508) =)$ 5,073,244, or $(5,073,244 \div 284,800 =)$ 17.81 tons of ice per 24 hours, showing that the loss due to the superheating of the gas only eight degrees in its passage from the refrigerator to the compressor amounted to $(17.81 - 17.49 =)$ 0.32 ton, or about one-third of a ton of ice per 24 hours.

If the liquid anhydrous ammonia piping between the condenser and the refrigerator and the ammonia gas piping between the refrigerator and compressor had been covered with a thoroughly non-conducting material, the refrigerating efficiency of the plant would have been :

Gas entering Compressor at	}	9,646 lbs.		
0° Fahr.....		5,411,406 Thermal units.		
Ammonia cooled from 62° to				
0° Fahr. (9,646 × 62 ×				
0.508).....		303,810	"	"

Effective Thermal Units = 5,107,596

or $(5,107,596 \div 284,800 =) 17.93$ tons of ice—being an increase of $(17.93 - 17.49 =) 0.44$, or nearly half a ton of ice per 24 hours.

As the question of condensing water has been fully discussed previously, it is considered unnecessary to go further into figures in relation to this part of the subject.

CHAPTER XI.

CALCULATION OF THE MAXIMUM CAPACITY
OF A MACHINE.

As the capacity of a machine is proportional to the quantity of anhydrous ammonia circulated, it is evident that if the ammonia valves are regulated so as to give a brine temperature of 0° Fahr., the refrigerating efficiency expressed in tons of ice will not be nearly so great as when the valves are adjusted for a 28° Fahr. brine temperature. The amount of anhydrous ammonia circulated at the former temperature would only be one-half the weight circulated at the latter temperature.

If the brine temperature were above 28° Fahr. it would be incapable of doing practical refrigerating work—that is, the temperature would be too high to freeze water sufficiently quick to be of any practical value.

Twenty-eight degrees Fahrenheit is therefore the highest practical brine temperature, and in order to maintain that the ammonia must boil at 14° Fahr., which latter temperature is obtained by regulating the ammonia valves so that a suction-gauge pressure of $28\frac{1}{4}$ lbs. is maintained.

Therefore, in calculating the maximum capacity of a machine we must figure upon the suction-gauge pressure being $28\frac{1}{4}$ lbs. and the suction temperature, say, 20° Fahr. at the point where the gas enters the compressor.

PREPARATION OF ANHYDROUS AMMONIA.

The principal parts of the apparatus necessary for the production of anhydrous ammonia from 26° ammonia are :

- (1) An iron cylinder (still) about 2 feet in diameter by 3 feet deep.
- (2) An iron cylinder (column) about 10 inches in diameter by 2 feet high.
- (3) A tank (condenser) about 3 feet in diameter by $4\frac{1}{2}$ feet deep.

(4) Two iron cylinders (separators) about 10 inches in diameter by $5\frac{1}{2}$ feet high.

(5) An iron vessel (dehydrator) about $3\frac{1}{2}$ feet long by 2 feet broad and 2 feet deep.

CONSTRUCTION OF APPARATUS.

The apparatus should be of sufficient strength to withstand a pressure of 60 lbs. on the square inch. Its general arrangement is shown in section in Fig. 15, in which A is the still, the contents of which is heated by the steam coil, *a*. The ammonia gas, together with a little water vapor, pass off through *b* into the column B, and coming in contact with the plates *c*, the larger portion of the water separates and flows back into A by the pipe *d*, while the ammonia gas passes upwards through the holes *e*, and over to the condenser, C. After leaving the condenser the gas passes through the two separators D, D (where the water condensed in C separates) into the dryer, E, where, coming in contact with lime placed on the perforated plates *f*, it is rid of its last traces of moisture.

It is then drawn through the pipe *l* into the suction of the ammonia engine.

The plates in B are separated by, and rest on, the iron rings *i*. The head of the still and bottom end-plate of B, together with the connections *b* and *d*, may be conveniently cast in one piece.

CONDENSER-WORM.

An efficient worm for the condenser, C, may be cheaply and easily made of heavy lead pipe.

It is advisable to place a cock or valve on the connection between B and C, so that when the spent water is drawn from the still, the gas contained in the rest of the apparatus will not escape. However, it is not absolutely necessary to have a cock or valve at that point, because if the water is carefully run off no gas will escape.

After the still, A, has been charged it is slowly heated by the coil, *a*, to a temperature of about 212° Fahr. When the gauge, *k*, registers 25 to 30 lbs. pressure the valve

connecting *l* with the suction of the compressor (of the ammonia engine) is opened and the engine run so as to maintain the pressure of 25 to 30 lbs.

WHY STILL IS WORKED UNDER PRESSURE.

The reason for running the still under a pressure is to enable the contents of the still being heated up to, or slightly above, the normal boiling-point of water without allowing the water to boil—thus driving off the whole of the ammonia, while only a minimum quantity of the water is vaporized.

After the still has been heated for about an hour, a small quantity (about a teaspoonful) should be drawn off and tested with acid litmus paper, and as soon as it ceases to turn the paper blue it may be understood that the contents of the still have been exhausted of ammonia and that the charge is “spent.”

BEST TEST FOR AMMONIA.

A better method for telling when the charge is spent, is to have a small cock in the head of the still, and, opening it slightly, test the escaping vapors with a piece of turmeric paper. If the paper is turned brown, the whole of the ammonia has not been driven off, but if it still retains its yellow color the charge is thoroughly exhausted.

The spent water is run off from the still by the cock *g*, and after the still has cooled down it is ready for re-charging.

WATER FROM SEPARATORS.

Very little water accumulates in the separators *D*, *D*, if the pressure in the still is carefully watched, but the cocks *h*, *h* should be cautiously opened (care being taken that no gas escapes) after about the fifth or sixth distillation, and if any water runs out it should be saved, as it will be saturated with ammonia gas, and therefore ought not to be thrown away, but should be placed in the drum containing the 26° ammonia.

LIME FOR DEHYDRATOR.

The lime in E should be examined occasionally by removing the hand-hole plate, F, and if it has slaked to any great extent the cover on E should be removed and the plates *f* taken out and replenished with newly burnt lime broken in pieces about the size of a hen's egg. The lime should not be laid more than one layer deep on each plate.

The amount of 26° ammonia that has to be distilled in order to obtain a given quantity of anhydrous ammonia can be determined by the use of Table II.

YIELD OF ANHYDROUS FROM 26°
AMMONIA.

Let it be supposed that 50 gallons of anhydrous ammonia are required. By referring to the table it is seen, under the heading "Per Cent. by Volume," that 26° ammonia contains 38.5 per cent. of anhydrous ammonia, therefore, as 50 gallons of anhydrous ammonia are required it will be necessary to

distill (38.5 : 50 :: 100) 130 gallons of 26° ammonia.

It is, of course, always advisable to try the strength of the 26° ammonia, as it is liable

TABLE II.

SOLUTION.			ANHYDROUS AMMONIA.			
Weight of In.		Boiling Point.	Volume of Gas (at 32° Fahr., and Atmospheric Pressure) In one Volume of the Solution.	Pounds in One Gallon of the Solution.	Per Cent. by Volume.	Per Cent. by Weight.

22.2	7.67	110°	244	1.520	29.4	19.7

to vary somewhat ; and should it be found stronger or weaker (*i. e.*, lighter or heavier in gravity) than the supposed strength, an allowance can be made, by means of Table II.,

when calculating the quantity necessary to be distilled to yield a given quantity of anhydrous ammonia.

The cost of preparing anhydrous ammonia from 26° ammonia is very small, and the difference in the price between the "home prepared" and the "commercial" anhydrous will very soon pay for the cost of the apparatus.

In most works where freezing plants are in use there are ample large-sized piping, small tanks or odd pieces of apparatus lying in disuse which could be easily fitted together on the principle of Fig. 15, and at a total cost of, say, \$150.

The price of commercial anhydrous ammonia is 44.88c. per lb., and the price of commercial 26° ammonia is 6c. per lb.

Twenty-six degree ammonia contains 26.6 per cent. by weight of anhydrous ammonia, therefore 3.76 lbs. of 26° ammonia give 1 lb. of anhydrous at a cost (irrespective of labor) of 22.56c.

SELDEN'S PATENT PACKING

Either with Rubber Core or Canvas Core. Guaranteed for Air, Ammonia, Steam and Water, if used in stuffing boxes.

"BRANDT'S TRIPLE EXPANSION GASKETS"

For Hand and Man-hole plates of boilers are the best, and used on the highest steam pressures.

RANDOLPH BRANDT,

38 Cortlandt Street, New York.

B. P. CLAPP AMMONIA COMPANY,

MANUFACTURERS OF

AQUA AND ANHYDROUS AMMONIA

OF THE BEST QUALITY.

For Refrigerating Purposes and the Trade.

OFFICE:

245 BROADWAY, NEW YORK.

GUILD & GARRISON,

Kent Avenue, corner South 10th Street,

BROOKLYN, N. Y.

AMMONIA PUMPS,

Brine Pumps, Boiler Feeders.

Practical Handbooks.

- Cromwell, J. H.—A System of Easy Lettering 50cts.
- Dahlstrom, K. P.—The Fireman's Guide. A handbook on the care of boilers. 28 pages, cloth, 50cts.
- Dubelle, G.—Formulas for the Soda Fountain. 493 receipts for making natural and artificial fruit syrups, extracts, essences, punches, flavorings, colorings, &c., &c. 157 pages, 12mo., cloth, 2.50
- Eldridge, J.—The Pump Fitters Guide, paper, 40cts.
- The Gas Fitters Guide, paper, 40cts.
- The Engineers Practical Guide for Fixing Hot Water Apparatus, 8vo., paper, 40cts.
- Fawkes, F. A.—Hot Water Heating on the Low Pressure System. 78 pages, illustrated, boards, 40cts.
- Graham, Maurice.—Practical Hints on the Construction and Working of Regenerator Furnaces. 131 pages, 50 illustrations, 16mo., limp leather, 1.25
- Higgs, W. P.—Algebra Self Taught. A valuable aid for Engineers preparing for Examination, .60
- Hornby, J.—The Gas Engineer's Laboratory Handbook. 304 pages, 83 illustrations, 12mo, cloth, 2.50
- Hughes, N.—The Magneto Hand Telephone: its construction, fitting up and use. 80 pages, 23 illustrations, 12mo, cloth, 1.00
- Ornamental Penmans Pocket Book of Alphabets, for Engravers, Sign Writers and Stone Cutters 20cts.
- Practical Electricians.—A universal handy book on everyday electrical matters. 135 pages, fully illustrated, 8vo, cloth, 75cts.
- Rowell, H.—Manual of Instruction in Hard Soldering. 56 pages, illustrated, cloth, 75cts.
- The Handy Sketching Book: for the use of engineers and draughtsmen. Sectional to EXACT eighths of an inch, blue lines, stiff boards, with useful tables, 25 cents each. Per dozen, \$2.50.
- We carry a large stock of Architectural, Building and Machine Drawing copies, price 10cts. each.
- Workshop Receipts: A valuable technical series in five volumes. Each volume complete in itself. \$2 each.

BOOKS OF REFERENCE.

AMERICAN ENGINEER AND RAILROAD JOURNAL.

AN ILLUSTRATED MONTHLY PUBLICATION.

Devoted to

**MECHANICAL ENGINEERING,
RAILROAD TOPICS AND INTERESTS.**

Due attention is given to such topics as Shop Practice, Tools, Machinery, Stationary and Marine Engineering, Naval Progress, New Inventions, Ordnance, New Publications, Proceedings of Engineering Societies, Condensed Notes and News, &c.

The special features enumerated, besides others, which are added from time to time, make it one of the most attractive journals now published for

**Engineers, Draughtsmen, Manufacturers,
Inventors, Mechanics and Students.**

SUBSCRIPTION PRICE.

North America - - - - - \$3.00

Foreign Countries in U. P. U. \$3.50

Single Copies - - - - - 25 cts.

**M. N. FORNEY, Editor and Proprietor.
